Facial affect recognition in individuals at clinical high risk for psychosis

Jean Addington, David Penn, Scott W. Woods, Donald Addington and Diana O. Perkins

Summary

Facial affect discrimination and identification were assessed in 86 clinical high-risk individuals and compared with 50 individuals with first-episode psychosis, 53 with multiphase schizophrenia and 55 non-psychiatric controls. On the identification task the non-psychiatric controls performed significantly better than all other groups, and on discrimination significantly better than both patient groups. Deficits in facial affect recognition appear to be present before the onset of psychosis and may be a vulnerability marker.

Declaration of interest

None. Funding detailed in Acknowledgements.

Social cognition is of interest in schizophrenia research, partly owing to its association with poor social functioning. Facial affect recognition is one component of social cognition and it has been well established that individuals with schizophrenia generally show deficits in both identification and discrimination of facial affect at all stages of the illness. These are stable deficits that appear to be unrelated to symptoms. Since social deficits often precede the onset of full-blown psychosis, the purpose of this paper was to determine whether facial affect deficits are present in people at clinical high risk for psychosis (i.e. putatively prodromal).

Method

The sample consisted of 86 individuals at clinical high risk for psychosis, 50 individuals with a first episode of psychosis, 53 with a chronic course of schizophrenia and 55 non-psychiatric controls. All clinical high-risk individuals are participants in the PREDICT study at the University of Toronto (n=34), the University of North Carolina (n=32) or Yale University (n=20), a three-site study determining predictors of conversion to psychosis. All clinical high-risk individuals met the Criteria of Prodromal States using the Structured Interview for Prodromal Symptoms. All participants met attenuated positive symptom state criteria, which included the emergence or worsening of a non-psychotic disturbance of thought content, thought process or perceptual abnormality over the past year.

facial affect recognition and information processing in schizophrenia (PANSS).6

Formal consent was obtained from all participants. Testing took place during two sessions, usually on the same day but always within a 7-day period. For PREDICT, all three sites participated in a rater training programme developed at Yale that teaches clinical researchers to identify the prodromal syndrome with good reliability.4 The kappa statistic was used to compare trainee agreement with the gold standard diagnosis of the presence or absence of a prodromal syndrome. Kappa was greater than 0.80 at all sites and the overall kappa was 0.90. J.A. chaired weekly conference calls to review criteria for every clinical high-risk individual admitted to the study. Facial affect recognition assessments were conducted by trained research assistants under the supervision of D.P. Detailed descriptions of quality training and good to excellent reliability for the data from all other participants has been described elsewhere.1

Results

All results are presented in Table 1. One-way ANOVAs were used to compare groups with Tukey post hoc tests to determine specific group differences. The groups differed significantly in age, with the multi-episode group being significantly older and the clinical high-risk group significantly younger. The first-episode, multi-episode and clinical high-risk groups did not differ on the General Psychopathology Scale of the PANSS. The multi-episode group rated significantly higher on positive symptoms than the first-episode group, with the clinical high-risk group in between without significantly differing from either. The clinical high-risk group had significantly lower ratings on negative symptoms than the first-episode and multi-episode groups.

A one-way between-groups MANOVA was performed to determine group differences on facial affect recognition, controlling for age. There was a statistically significant difference between groups on the combined dependent variables (F[4, 240]=6.27; P=0.0001; Wilks’ λ=0.86; partial η²=0.07). Both the identification task (F[2, 242]=10.13; P=0.0001; partial η²=0.11) and the discrimination task (F[2, 242]=5.52; P=0.001; partial η²=0.07) were statistically significant. The one-way ANOVA (Table 1) demonstrates that on the identification task, the control group performed significantly better than the clinical high-risk and patient groups. On the discrimination task, patient groups performed significantly more poorly than the control group, and the performance of the clinical high-risk group fell between that of the patient and control groups without significantly differing from either.

Discussion

This is one of the first studies to examine facial affect recognition in a group of individuals at high risk of developing psychosis. A previous study did not detect any differences between control individuals and a very small (n=19) clinical high-risk sample.3 The young people in our at-risk sample were seeking help and had significant disability. Their ability to identify emotions did not differ from the patient groups and was significantly worse than the control group. Their ability to differentiate emotions did not differ significantly from either group, most likely because the discrimination task is less difficult than the identification task.1 It has been suggested7 that such deficits may be vulnerability factors in that subtle deficits in affect perception were detected in unaffected biological siblings of patients with schizophrenia. Our study suggests that these deficits are present, before the full expression of a psychotic illness, in high-risk individuals of whom only about 25% will go on to develop a full-blown psychotic illness.8

Our study has limitations. It is cross-sectional and does not address predictors of conversion. The control individuals are at a different site but do demonstrate results consistent with the rest of the literature. There was no control task to determine whether the impairment was specific to emotions or is generalised, although results of using a differential design in the literature are mixed.1 The strengths of our study are the reasonably large numbers in each group, the well-defined clinical high-risk group and the use of three control groups.

There may be implications for affect recognition deficits in the conversion to psychosis that can be examined only in longitudinal studies. In addition, if we want to better understand the social decline observed prior to the onset of psychosis, future studies should examine the relationship between social functioning, affect recognition and cognition.1

Acknowledgements

This study was supported by NIMH grants: U01MH066134 to J.A., U01MH066069 to D.P. and U01MH066160 to S.W. J.A. also received a grant from the Canadian Institutes of Health Research.
